A novel type of deep anterior lamellar keratoplasty (DALK) using limited pneumatic dissection (small bubble) has been performed for the treatment of stromal corneal opacities or ectasia that occurs after penetrating keratoplasty (PK). The standard procedure included deep trephination (70%-80% of thickness) outside the old PK wound, centripetal advancement of a cannula from the base of the incision across the PK wound, slow pneumatic dissection of the central cornea within the PK wound, removal of the centrally detached stroma and manual dissection of the residual surrounding tissue up to the trephination, and suturing of donor tissue deprived of its endothelium. The small bubble DALK is a viable and effective alternative to additional PK for the replacement of the diseased stroma of a full-thickness graft with healthy endothelium. It shares the optical advantages of PK and the safety of an anterior lamellar keratoplasty, avoiding the risks of open eye surgery.

**Surgical Procedure**

In all patients, anesthesia was administered with peribulbar injection of a mixture of 5 mL each of lidocaine hydrochloride, 2%, and bupivacaine hydrochloride, 0.5% (Video). A Barron suction trephine (Katena Products Inc) was centered on the corneoscleral limbus, and a circular incision 8 to 9 mm in diameter, was made, taking care to include the original PK wound (Figure 1A and B); thus, the graft size was enlarged compared with the original PK in an attempt to minimize postoperative astigmatism. To minimize the risk of perforation, trephination to approximately 70% to 80% of the thickness measured by anterior segment optical coherence tomography was purposely performed outside and not inside the often irregular PK wound. A blunt 27-gauge cannula was inserted at the base of the incision and advanced centripetally across the PK wound; air was injected with minimal pressure to obtain a bubble within the margin of the PK wound (Figure 1C). After manual removal of the superficial stroma, the bubble was entered with a 30° blade, and the deep stroma was excised, barring DM over an optical area 5 to 6 mm in diameter (Figure 1D). Predescemetic dissection of the residual peripheral rim was performed manually (Figure 1E).

A Barron donor punch (Katena Products Inc) was used to prepare a full-thickness graft (same size as the trephination in the recipient cornea) from which DM and endothelium were stripped off using a dry Weck-Cel sponge. The donor tissue was fixated with 4 cardinal sutures that were removed after completing the procedure with a double running 10-0 nylon suture (Figure 1F). These sutures were removed in all cases within 12 months.

**Results**

Nine eyes from 9 patients with a history of PK who had undergone small-bubble DALK were identified. The indications for subsequent surgery were corneal ectasia (n = 4), scarring after stromal melt (n = 2), post–photorefractive keratectomy haze (n = 2), and recurrence of dystrophy (n = 1) (Figure 2). In all cases, the pathologic findings did not extend outside the PK wound.
Figure 1. Surgical Steps of Small-Bubble Deep Anterior Lamellar Keratoplasty

A. Recurrent ectasia in an eye with a decentered penetrating keratoplasty (arrowheads). B. Trephination, 8.5 mm in diameter, up to 70% to 80% of peripheral corneal thickness. C. Air injection into deep stroma by means of a blunt 27 gauge cannula to achieve a bubble 5 to 6 mm in diameter. D. After removal of the superficial stroma, baring of the Descemet membrane with blunt corneal scissors. E. Manual predescemetian dissection and removal of the residual peripheral deep stroma. F. Fixation of donor tissue with 2 running 10-0 nylon sutures.
Figure 2. Results of Small-Bubble Deep Anterior Lamellar Keratoplasty Performed in Eyes With Recurrent Ectasia After Penetrating Keratoplasty

A. Preoperative slitlamp appearance. B. Anterior segment optical coherence tomography (AS-OCT). C. Corneal topography of an eye with recurrence of ectasia 6 years after penetrating keratoplasty. D. Three months after small-bubble deep anterior lamellar keratoplasty, the cornea is perfectly clear with no sign of ectasia. E. Area of peripheral manual dissection as seen with AS-OCT (arrow). F. Fifteen months after surgery, corneal topography reveals the presence of low-degree regular astigmatism.
Intraoperative complications included failure to form the bubble (n = 1) and microperforation that occurred during manual dissection of the peripheral stroma (n = 1). In both cases, the procedure was completed by means of manual dissection, even in the former case obtaining a final central thickness of the recipient bed of approximately 30 μm as measured postoperatively by anterior segment optical coherence tomography.

Demographic data and results are summarized in the Table. At the latest follow-up examination (14 months after surgery), all sutures were removed in all 9 eyes, and best spectacle-corrected visual acuity had improved by at least 4 Snellen lines; refractive astigmatism had improved in all 4 patients with corneal ectasia and in 3 of the 5 eyes with stromal opacities. Endothelial cell density was not significantly affected by surgery. No postoperative complications were recorded.

Discussion

Anterior lamellar keratoplasty (ALK) is becoming increasingly popular because of its main intrinsic advantage of replacing diseased stroma while sparing healthy endothelium. Although microkeratome-assisted ALK in post-PK eyes is relatively simple and quick to perform, it is not recommended for stromal lesions that extend beyond a depth of 200 μm or for advanced corneal ectasia because of the risk of perforation. Instead, manual dissection is a painstaking maneuver, often yielding disappointing visual results and requiring conversion to PK in a relatively high number of cases.

The small-bubble DALK technique uses an approach similar to that of the big-bubble technique described originally by Anwar and Teichmann. However, pneumatic dissection with small-bubble DALK is limited only to the central 5 to 6 mm, thus eliminating the risk of bursting the bubble when the scar between donor and recipient DM is reached. The size of the optical zone with bare DM was sufficiently large to allow excellent visual results in all cases. Irregularities in the peripheral residual stroma that result from manual dissection are visually irrelevant when located outside the optical zone and may instead lead to a stronger wound profile, as has been reported for mushroom keratoplasty.

As with any procedure that uses pneumatic dissection, creation of the bubble may fail but can be handled more easily, as was done in one eye of this series, because the critical maneuver of removing DM by hand is required over a much smaller area than with conventional big-bubble procedures. In addition, Lim and Lim have reported the use of manual dissection of the peripheral residual recipient stroma between bare DM and the trephination cut to manage incomplete bubble formation. Their method, proposed for eyes without previous PK surgery, supports the same concept applied by us in post-PK eyes: dissection does not need to further expose DM but rather simply modify the recipient bed to allow proper allocation of the donor tissue. Large grafts of 9 mm or larger in diameter can therefore be used with the same risk of smaller grafts, while increasing the chances of a more regular postoperative corneal curvature. Finally, if microperforations or a dehiscence of the PK wound occurs, completion of the procedure by manual dissection can be attempted similarly to the big-bubble technique.

Conclusions

Small-bubble DALK is a viable and effective procedure for treating recurrence of ectasia or stromal opacities that develop after PK; visual acuity is significantly improved, and complications can be managed with no need for conversion to full-thickness transplantation.
